The flow of droplets of bio-pesticide, liquid laden with entomopathogenic nematodes (EPNs), over foliage approximated as a planar substrate is investigated theoretically via a simple analytical model and computationally by solving a subset of the Navier-Stokes equations arising from application of the long-wave approximation. That the droplets of interest can be represented as a homogeneous liquid is established via complementary experiments revealing the presence of EPNs to have negligible influence on bio-pesticide droplet spray distribution predeposition. Both approaches are used to study key issues affecting the migration of droplets over substrates relevant to pesticide deposition processes, including the effect (i) of droplet size and flow inertia on droplet morphology and coverage and (ii) of adaxial (above the leaf) or abaxial (under the leaf) flow orientations. The computational results obtained when inertia is accounted for are generally found to compare well with those given by the simple analytical model — a droplet’s velocity relaxes to its terminal value very quickly, at which point gravitational, viscous, and hysteresis forces are in balance; substrate orientation is found to have only a minor influence on the extent of droplet migration.

KEY WORDS: droplets, fluidflow, experiments, analysis, computations, bio-pesticide

1. INTRODUCTION

The migration of droplets residing on a substrate is ubiquitous throughout science and engineering, and is crucial to several natural, engineering and manufacturing processes. Important examples are encountered in the deposition of coatings and inks, in enhanced oil recovery, the direct patterning of functional layers during microchip production, and the cooling of electronic components [see, for example, Bear, 1988; Gaskell et al., 2008; Anandan and Ramalingam, 2008]. The motion of such droplets can be induced in several ways: electrostatically (Kim et al., 2002), via temperature or chemical gradients (Tseng et al., 2004), due to shearing from the movement of a surrounding fluid, usually air (Ding and Spelt, 2008), and, of particular relevance here, by gravity (Le Grand et al., 2005; Schwartz et al., 2005), the environmental driver being the need to achieve more efficient and sustainable usage of pesticides. In addition, since legislation is limiting the use of chemically active pesticides for pest control in crops, the present focus is the study of droplet motion relevant to bio-pesticides involving entomopathogenic nematodes (EPNs) as components of an integrated pest management system (Matthews, 2000).
Several previous experimental, analytical, and computational studies of droplet motion over substrates provide important knowledge and information relevant to pesticide deposition on foliage; see, for example, the review of Yarin (2006) concerning the fundamental dynamics associated with droplet impact, splashing, and spreading. Other experimental investigations include the distortion and pearling of gravity-driven droplets on an inclined plane (Podgorski et al., 2001; Le Grand et al., 2005), and, more recently, ones involving the movement of droplets due to shearing air flows (Fan et al., 2011), together with the impact and/or coalescence of deposited surface droplets (Kapur and Gaskell, 2007; Castrejon-Pita et al., 2011). These are complemented by more applied experimental explorations which have focused on key practical spreading indicators such as the evolution of droplet radii with time, droplet spread factors (ratio of final to initial cross-sectional area), and droplet evaporation times. Another important consideration, since agrochemical products typically contain between 1 and 10% of one or more surfactants, concerns the key role of adjuvants and the resultant effects on dynamic surface tension, which have also been investigated widely (Xu et al., 2011). Several researchers have quantified how the addition of adjuvants leads to larger spread factors and a reduction in evaporation time, enabling smaller droplets to be retained on difficult-to-wet foliage.

It is recognized that a better understanding of droplet migration over foliage via modelling can play an important role in achieving optimum pesticide usage by providing greater understanding of the key influences of droplet size, impact velocity, constituent parameters, and foliage properties (Teske et al., 2011). Several useful models have already been developed to predict droplet behaviour on solid substrates [see, for example, Deegan et al. (2000) and Cachile et al. (2002)], many of which simplify the governing equations for situations where flow inertia is deemed negligible. Recent studies have focused on incorporating more complex physics into such flow models, such as the influence of surfactants (Chengara et al., 2007), humidity levels (Dunn et al., 2008), substrate thermal conductivity (Dunn et al., 2009), and have been highly successful in modelling 2-D and axisymmetric flow phenomena on homogeneous substrates.

In terms of obtaining complex three-dimensional numerical solutions to such free-surface flow problems, the significant computational challenges and resource requirements involved have led to very few results, based on solving the full Navier-Stokes equations, appearing in the literature to date. Those that do have employed, in the main, the topological flexibility of finite element (FE) methods coupled with Arbitrary Lagrangian-Eulerian (ALE) techniques for tracking free-surface locations. Examples include the study of free-surface flow with wetting lines by Baer et al. (2000) and simulations of injection moulding by Wang and Li (2010). The lattice Boltzmann method is also showing promise for simulating droplet flows and offers potentially significant advantages over FE-based methods in terms of topological flexibility and scalability for high performance computing applications; see the recent exploration of droplet impact and coalescence by Castrejon-Pita et al. (2011).

The above computational drawbacks in relation to solving free-surface flows in general, and droplet flows in particular, have motivated the development of a range of efficient numerical methods in the last decade or so based on simplifying the full Navier-Stokes equations via the long-wave approximation in situations where the fact that the characteristic film thickness/height is small compared to the characteristic in-plane length scale can be exploited. The additional simplifying assumption of negligible inertia enables the flows to be represented by either a single fourth-order nonlinear degenerate partial differential equation for the film thickness or a coupled set of equations for the film thickness and pressure, albeit with formal restrictions to surface tension-dominated flows with small capillary number (Lee et al., 2009; Gaskell et al., 2010; Cowling et al., 2011). By employing a precursor film model to alleviate the singularity associated with the three-phase contact lines present, this so-called lubrication model (Oron et al., 1997) has been used successfully to investigate a variety of droplet flows at zero Reynolds number. Examples include flow over homogeneous substrates with (Schwartz et al., 2001), and without (Glass et al., 2010) evaporation, with surfactants (Schwartz et al., 2004), and for a non-Newtonian power-law liquid (Ahmed et al., 2013) over heterogeneous substrates with variable wettability (Schwarz and Eley, 1998) and containing, in addition, microscale topographical features (Gaskell et al., 2004). A key challenge is achieving mesh-independent solutions (Koh et al., 2009), and spreading rates quantitatively comparable with those observed experimentally (Gaskell et al., 2008).

Since the influence of inertia on free-surface flow can be important in terms of surface deformation and stability, lubrication-type models for continuous thin-film flows at nonzero Reynolds number have appeared; see, for example, Veremieiev et al. (2010), who developed a depth-averaged approach, akin to the integral boundary layer equations first reported by Shkadov (1967, 1968), for exploring such problems. Related experiments, other than in the low-
Reynolds-number regime, have lagged behind. However, Puthenveettil et al. (2013) have recently addressed this issue and reported a comprehensive set of experimental results, data, and visualizations for the motion of water and mercury droplets on an inclined plane surface in, as they term it, the inertial regime. They derive an analytical expression for the dimensionless velocity of their drops, covering the Reynolds number range explored, and compare their dynamic contact angle data to models that have appeared in the literature.

The following section gives a brief description of an experimental study into the effect of adding EPNs and a commercial adjuvant on droplet size distribution in bio-pesticide sprays. In Sec. 3 both an analytical model and one involving the numerical solution of a governing equation set based on application of the long-wave approximation, for droplet flow over an inclined planar substrate, are presented. The results provided in Sec. 4 consider the influence of droplet parameters, flow inertia, and leaf orientation on droplet migration, with predictions compared against experimental data; conclusions are drawn in Sec. 5.

2. EXPERIMENTAL MEASUREMENT OF BIO-PESTICIDE DROPLET SIZE DISTRIBUTION

Bio-pesticides utilise living organisms to kill pests with the use of EPNs which attack pests by entering body openings and releasing bacteria that prevent pests from feeding becoming increasingly popular. Commercial bio-pesticides are prepared by mixing EPNs in a carrier solution and then mixing this with water and adjuvants before spraying onto leaves. In order to determine the influence of EPNs on droplet size distribution and hence if the droplets produced behave as a homogeneous liquid, a series of experiments was carried out with water and different concentrations of a commercial adjuvant supplied by Becker Underwood. The commercial bio-pesticide, which includes 10% carrier material with the infective juvenile stage nematodes Steinernema Feltiae, was mixed with water and adjuvant to give a nematode concentration of 125,000/L. Sprays were generated using a Teejet XR11005 nozzle at a pressure of 0.8 bar.

Spray size measurements were carried out using the Malvern Spraytec laser diffraction system, which is based on the principle that particles passing through a laser beam scatter light at an angle directly related to their size; the diffraction pattern is transformed into a particle size distribution using Lorenz-Mie theory for the scattering of electromagnetic radiation by spherical particles. Measurements were averaged over time and at three different locations A, B, and C of the spray, as indicated in Fig. 1.

The reported volume median diameter (VMD) Dv0.5 is defined as the droplet diameter where half of the spray droplets have a smaller diameter. The experiments performed revealed both the carrier material and the EPNs to have a minor influence on the droplet size distribution of the spray when compared with the same for a water-adjuvant-only control. Table 1 shows the influence of adjuvant concentration on the VMD of the spray. Low concentrations of

adjuvant have little effect on the VMD; however, the latter increases significantly when the adjuvant concentration is increased to 0.3% and beyond. Since the EPNs represent a very small proportion of the total droplet volume (Lello et al., 1996), these findings are significant and sufficient to suggest that droplets of bio-pesticide can be suitably modelled by assuming them to be essentially a homogeneous liquid for droplets in flight and postdeposition.

3. DROPLET FLOW MODELS

Two models have been formulated to investigate the problem of interest, namely, droplet flow on planar substrate postdeposition: one results in analytical expressions for the terminal velocity and relaxation time of such droplets, based on a simple force balance argument; and the other leads to a coupled governing partial differential equation set that is solved numerically and from which the associated predicted terminal velocity and relaxation times are extracted.

3.1 Analytical Formulation

Figure 2(a) is a schematic of the sideview, at time \(T\), of a liquid droplet of volume \(V_0\), having initial velocity \(U_0\), flowing down a substrate inclined at an angle \(\alpha\) to the horizontal, where the chosen Cartesian streamwise \(X\) and normal \(Z\) coordinates are as indicated. The liquid is assumed to be incompressible and to have constant density \(\rho\), dynamic viscosity \(\mu\), and surface tension \(\sigma\). The motion of the droplet is governed by competing gravitational, drag, and hysteresis forces, and Newton’s second law applied down the substrate yields

\[
\rho V_0 \frac{dU_c}{dT} = \rho g_0 V_0 \sin \alpha - F_{\text{drag}} - F_{\text{hyst}},
\]

where \(g_0\) is the standard gravity constant, \(U_c\) is the droplet’s velocity at any time, \(F_{\text{drag}} = c_s \mu L_0 U_c\) is the viscous drag on the droplet, \(L_0 = V_0^{1/3}\) is the characteristic size of the droplet, \(c_s\) is the dimensionless Stokes drag coefficient, \(F_{\text{hyst}} = \sigma L_0 \Delta\) is the interfacial force due to contact angle hysteresis, and \(\Delta\) is the dimensionless hysteresis coefficient. \(F_{\text{hyst}}\) arises due to the heterogeneous nature of foliage, where scanning electron microscopy reveals a large diversity

FIG. 2: Schematic diagram of (a) the forces acting on a droplet migrating over an inclined planar substrate, shown in cross-section, and (b) three-dimensional droplet flow over an inclined planar substrate.
of leaf microstructures (Koch et al., 2009) that lead to significant local variations in wettability. Including such small-scale variations in substrate properties is currently not feasible, so the popular approach is to model them by specifying different substrate contact angles for advancing and receding contact line motion (Glass e al., 2010).

Inserting $F_{\text{drag}}$ and $F_{\text{hyst}}$, as defined above, in Eq. (1) and integrating yields

$$U_e = U_t \left(1 - e^{-T/T_e}\right) + U_0 e^{-T/T_e},$$

with the droplet’s terminal (asymptotic) velocity and relaxation time to terminal velocity given by

$$U_t = \frac{\rho g L_0^2 \sin \alpha - \sigma \Delta}{c_s \mu}$$

and

$$\tau = \frac{\rho L_0^2}{c_s \mu},$$

respectively. The minimum volume $V_0^{\text{min}}$ of the smallest droplet that is able to move over the substrate is found by setting $U_t = 0$ in Eq. (3):

$$V_0^{\text{min}} = \left(\frac{\sigma \Delta}{\rho g_0 \sin \alpha}\right)^{3/2}.$$  

Equations (3) and (5) are the same as relations (5.2) and (5.3) from Dussan (1985); Eq. (3) can also be expressed in dimensionless form as follows:

$$c_s \text{Ca} = Bo - \Delta,$$

where $Bo = \rho g_0 L_0^2 \sin \alpha / \sigma$ is the Bond number, measuring the relative importance of the $X$-component of gravity to surface tension forces and Ca = $\mu U_0 / \sigma$ is the capillary number, measuring the relative importance of the viscous forces to surface tension forces. The Reynolds number, measuring the relative importance of inertial to viscous forces, is defined as $Re = \rho U_1 L_0 / \mu$.

Le Grand et al. (2005) reported experimentally obtained dimensionless hysteresis coefficient values $\Delta^{\text{exp}}$ close to the theoretical ones $\Delta^{\text{th}}$ obtained for Ca $\ll 1$ and Re $\ll 1$ (Dussan, 1985), given by

$$\Delta^{\text{th}} = \left(\frac{24}{\pi}\right)^{1/3} \frac{(\cos \theta_r - \cos \theta_a) (1 + \cos \theta_a)^{1/2}}{(2 + \cos \theta_a)^{1/3} (1 - \cos \theta_a)^{1/6}},$$

where $\theta_a$ and $\theta_r$ are the advancing and receding contact angles made with the substrate, respectively (see Table 2). In the present study comparisons are also made of the experimental values for $c_s$, $c_s^{\text{exp}}$ with the theoretical ones from Dussan (1985):

$$c_s^{\text{th}} = \left(\frac{\partial \theta_a}{\partial \text{Ca}} + \frac{\partial \theta_r}{\partial \text{Ca}}\right) \frac{\sin^2 \theta_a}{2} \left(\frac{3 \pi^2}{2 - 3 \cos \theta_a + \cos^3 \theta_a}\right)^{1/3},$$

where $\partial \theta_a / \partial \text{Ca}$ and $\partial \theta_r / \partial \text{Ca}$ are inverse contact line capillary numbers that are characterized by the wetting dynamics; their values are taken from Fig. 18 of Le Grand et al. (2005) for 47V10, 47V100, and 47V1000 liquids and for water from Puthenveettil et al. (2013). Other related data from Podgorski et al. (2001) and Kim et al. (2002a) are also provided in Table 2 for completeness. $\Delta^{\text{th}}$ is found to be 32% larger than its experimental counterpart $\Delta^{\text{exp}}$ from the work of Podgorski et al. (2001). For the Le Grand et al. (2005) $\Delta^{\text{exp}}$, while $c_s^{\text{th}}$ is 16% greater than the experimental estimate $c_s^{\text{exp}}$. With reference to the data of Puthenveettil et al. (2013), $\Delta^{\text{th}}$ is within 1% of $\Delta^{\text{exp}}$, while $c_s^{\text{th}}$ is found to be 13% greater than the $c_s^{\text{exp}}$ estimate.

Although the above comparison shows that this simple analytical model is a useful guide for steady droplet flows, as Bo ($L_0$) increases the experimental data of Podgorski et al. (2001) and Le Grand et al. (2005) shows that the linear relationship between Ca and Bo, predicted by Eq. (6), breaks down when cusps develop at the rear of a moving droplet. Such droplet distortions, which eventually lead to secondary, pearl droplets (Schwartz et al., 2005; Koh et al., 2009), are able to be predicted via numerical solutions of the model described below.
TABLE 2: Comparison between $\Delta^{\text{exp}}$ and $c_{\pi}^{\text{exp}}$ [inferred from data presented in (a) Podgorski et al. (2001), (b) Kim et al. (2002a), (c) Le Grand et al. (2005), and (d) Puthenveettil et al. (2013)] with $\Delta^{th}$, Eq. (7), and $c_{\pi}^{th}$, Eq. (8), respectively.

3.2 Depth-Averaged Form (DAF): Numerical Formulation

Figure 2(b) is a schematic of the three-dimensional droplet motion of interest. The Cartesian streamwise $X$, spanwise $Y$ and normal $Z$, coordinate system adopted is as indicated, with the solution domain bounded from below by the surface $Z = 0$, from above by the free surface $Z = H(X, Y, T)$, upstream and downstream by the inflow $X = 0$ and outflow $X = L_0$ planes, respectively, and to the left and right by the side planes at $Y = 0$ and $Y = W_p$. The variable $H$ is a priori unknown, and the laminar flow is described by the Navier-Stokes and continuity equations, namely

$$ p \left( \frac{\partial U}{\partial t} + U \cdot \nabla U \right) = -\nabla P + \mu \nabla^2 U + pG, $$  \hspace{1cm} (9)

$$ \nabla \cdot U = 0, $$  \hspace{1cm} (10)

where $U = (U, V, W)$ and $P$ are the fluid velocity and pressure, respectively, and $G = g_0 (\sin \alpha, 0, -\cos \alpha)$ is the acceleration due to gravity.

Solving Eqs. (9) and (10) subject to appropriate boundary conditions is extremely challenging, and the associated computational resource requirements mean that such solutions are rare. The significant computational challenges of simulating droplet flows can be alleviated using the so-called long-wave approximation based on an assumption that the ratio $\varepsilon = H_0/L_0 \ll 1$, where $H_0$ is the characteristic initial droplet height. Following Gaskell et al. (2004), all analyses are performed and results presented in terms of corresponding nondimensional (lower case) variables, the key ones being

$$(x, y) = \left( \frac{X}{L_0}, \frac{Y}{L_0} \right), \quad (z, \text{\pi}) = \left( \frac{Z}{H_0}, \frac{T}{T_0} \right), \quad t = \frac{T U_0}{L_0}, \quad p = \frac{L_0 P}{\sigma \varepsilon}, \quad \left( \frac{u, v, w}{\varepsilon} \right) = \left( \frac{U, V, W}{U_0} \right).$$  \hspace{1cm} (11)

The resulting depth-averaged form (DAF) of the governing continuity and Navier-Stokes equations [see Veremieiev et al. (2010) for the full details] retains the following inertia terms:

$$ \frac{\text{Re}_0 \text{Ca}_0}{\varepsilon} \left( \frac{\partial \bar{u}}{\partial t} - \frac{\bar{u}}{5h} \frac{\partial h}{\partial t} + \frac{6}{5} \left( \frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} \right) \right) = -\frac{\partial p}{\partial x} - \frac{3\text{Ca}_0 \bar{u}}{\varepsilon^3 h^2} + \frac{\text{Bo}}{\varepsilon}, $$  \hspace{1cm} (12)

$$ \frac{\text{Re}_0 \text{Ca}_0}{\varepsilon} \left( \frac{\partial \bar{v}}{\partial t} - \frac{\bar{v}}{5h} \frac{\partial h}{\partial t} + \frac{6}{5} \left( \frac{\partial \bar{v}}{\partial x} + \frac{\partial \bar{v}}{\partial y} \right) \right) = -\frac{\partial p}{\partial y} - \frac{3\text{Ca}_0 \bar{v}}{\varepsilon^3 h^2}, $$  \hspace{1cm} (13)

$$ \frac{\partial h}{\partial t} + \frac{\partial}{\partial x} (h \bar{u}) + \frac{\partial}{\partial y} (h \bar{v}) = 0, $$  \hspace{1cm} (14)

$$ p = - \left( \frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} \right) + \text{Bo} \cot \alpha (h - \text{\pi}) - \Pi(h), $$  \hspace{1cm} (15)
where \( C_a = \mu U_0 / \sigma \) and \( Re_0 = \rho U_0 L_0 / \mu \) are the capillary and Reynolds numbers based on the initial velocity \( U_0 \), the overbar denotes depth-averaged components of velocity, namely,

\[
\bar{u} = \frac{1}{h} \int_0^h u \, dz, \quad \bar{v} = \frac{1}{h} \int_0^h v \, dz.
\]

(16)

In Eq. (15), a disjoining pressure \( \Pi(h) \) has been introduced to alleviate the singularity that would otherwise occur at the droplet’s dynamic contact line, where \( \Theta \) is the liquid’s dynamic contact angle with the substrate, \( h^* \) is the precursor film thickness, and the constants \( n \) and \( m \) are exponents of the interaction potential (Schwarz and Eley, 1998):

\[
\Pi(h) = \frac{(n - 1)(m - 1)(1 - \cos \Theta)}{\varepsilon^2 h^*(n - m)} \left[ \left( \frac{h^*}{h} \right)^n - \left( \frac{h^*}{h} \right)^m \right].
\]

(17)

In the results reported subsequently, inertialess flows are modelled by setting the left-hand sides of Eqs. (12) and (13) to zero, while the effect of leaf heterogeneity is modelled in terms of its advancing (\( \Theta_a \)), receding (\( \Theta_r \)), and equilibrium (\( \Theta_e \)) contact angles as follows:

\[
\Theta = \begin{cases} 
\Theta_a, & \frac{\partial h}{\partial t} > 0, \\
\Theta_r, & \frac{\partial h}{\partial t} < 0, \\
\Theta_e, & \frac{\partial h}{\partial t} = 0.
\end{cases}
\]

(18)

Equations (12)–(15) are solved subject to symmetry boundary conditions at the edges of the computational domain, namely,

\[
\frac{\partial (\bar{u}, \bar{v}, p, h)}{\partial x} \bigg|_{x=0,} = \frac{\partial (\bar{u}, \bar{v}, p, h)}{\partial y} \bigg|_{y=0,} = 0.
\]

(19)

At the start of the motion, all droplets have center of mass velocity \( U_0 \) and are assumed to be elliptic paraboloids defined by

\[
h(x, y, 0) = \max \left[ 1 - \frac{(x-x_0)^2 + (y-y_0)^2}{r_0^2}, h^* \right],
\]

(20)

where \( x_0 \) and \( y_0 \) are the initial coordinates of the center of mass of the droplet, while the velocity components are set to \( \bar{u}(x, y, 0) = 2h^2 \) and \( \bar{v}(x, y, 0) = 0 \). Using the relation for dimensionless volume \( 1/\varepsilon = \pi r_0^2 / 2 \) and contact angle of the paraboloid \( \tan \Theta_e = 2\varepsilon / r_0 \), the in-plane dimensionless radius \( r_0 = (4/\pi \tan \Theta_e)^{1/3} \) and long-wave ratio \( \varepsilon = (\tan^2 \Theta_e / 2\pi)^{1/3} \) are obtained. From the latter expression it follows that the long-wave approximation \( \varepsilon \ll 1 \) is not applicable if \( \Theta_e \) is too large, although results suggest that it can remain valid outside of this formal range of applicability.

The above equations, subject to the attendant boundary conditions, are solved on a rectangular computational domain \( (x, y) \in \Omega = (0, l_x) \times (0, l_y) \), subdivided using a staggered arrangement of unknowns, consisting of \( n_x \) and \( n_y \) regular cells in the \( x \) and \( y \) directions, respectively. The unknown variables, thickness \( h \), pressure \( p \), and velocity components \( (\bar{u}, \bar{v}) \) are located at cell centers \( (i, j) \) and cell faces \( (i + 1/2, j), (i, j + 1/2) \), respectively. An automatic adaptive time-stepping procedure that utilizes estimates of the local truncation error to optimize the size of the time steps and minimize computational cost is employed. At the solution stage of the temporal discretization, the system of equations is solved using a customized multigrid strategy. The discretized equations are solved using a fixed number of full approximation Storage V-cycles on intermediate grid levels and up to 10 V-cycles on the first grid level so that residuals are reduced below a specified tolerance. Further details concerning the spatial and temporal discretization schemes and the multigrid solution method are available in Veremieiev et al. (2010).
4. RESULTS

The effect of droplet volume, inertia and substrate orientation on droplet migration over a heterogeneous substrate are explored. Numerical results are obtained for an initial droplet speed $U_0 = 0.5$ m/s and when the physical parameters of the liquid are set to: $\rho = 1000$ kg/m$^3$, $\sigma = 0.0632$ N/m, $\mu = 0.00142$ Pa · s, based on a 0.1% concentration adjuvant solution in water, with $\theta_e = 45^\circ$, $\theta_a = 50^\circ$, $\theta_r = 40^\circ$, $h^* = 0.01$, $m = 2$, $n = 3$, $l_p = 20 r_0$, $w_p = 5 r_0$, $x_0 = 5 r_0$, $y_0 = 2.5 r_0$, $n_x = 512$, $n_y = 128$.

4.1 Effect of Droplet Geometry and Inertia

Figures 3 and 4 show the effect of increasing Bo (increasing $L_0$) on the flow of different droplets down an inclined plane ($\alpha = 60^\circ$) without ($Re_0 = 0$) and with inertia ($Re_0 \neq 0$), respectively. For flow without inertia the shape of the droplet footprint remains approximately circular. Figure 4 shows that the inclusion of inertia, leads to an initial elongation of the droplet footprint before relaxation toward an asymptotic quasicircular footprint at later times. For

FIG. 3: Droplet motion, from left to right, down an inclined planar surface viewed at various times showing the effect of Bo ($L_0$). DAF ($Re_0 = 0$) solutions obtained for $\alpha = 60^\circ$.

FIG. 4: Droplet motion, from left to right, down an inclined planar surface viewed at various times showing the effect of Bo ($L_0$). DAF ($Re_0 \neq 0$) solutions obtained for $\alpha = 60^\circ$.
the droplet with the largest considered Bond number, $Bo = 0.62$ ($L_0 = 2.2 \text{ mm}$), there is a particularly large initial elongation which leads to a long tail; however, this subsequently relaxes toward a quasicircular droplet footprint.

Figure 5 shows the effect of increasing droplet size on the evolution of the velocity of the center of mass of the droplet $U_c$ calculated via

$$U_c = U_0 \int \int_{(x,y) \in (h > h^*)} \bar{u} h dx dy.$$  \hfill (21)

Note that in Figs. 5 and 8 the analytical curves (2) and (6) are obtained using the experimental values of $c_{s}^{\exp} = 150$ and $\Delta^{\exp} = 0.17$ from Le Grand et al. (2005) for the flow of 47V10 fluid, whose viscosity is the closest to that of the 0.1% concentration adjuvant solution in water. For the cases where inertia is neglected, the DAF predicts that $U_c$ relaxes to the terminal velocity much more quickly than the simple analytical model predicts, while the inclusion of inertia increases the relaxation time significantly and reduces the terminal velocity. This is shown in greater detail in Tables 3 and 4, which compare DAF predictions of the terminal migration velocity $U_t$ and droplet velocity relaxation time $\tau$ against the corresponding analytical predictions given by Eqs. (3) and (4), respectively, obtained for $c_{s}^{\exp} = 150$ and $\Delta^{\exp} = 0.17$.

For the case with flow inertia, Table 4 shows that both $U_t$ and $\tau$ increase monotonically with droplet size. The analytical and DAF predictions of the relaxation time $\tau$ for inertial flows are in excellent agreement in all cases. Agreement between the two predictions of $U_t$ improves as droplet size increases and is reasonably good for the larger droplets. However, for the smallest droplet, $Bo = 0.06$ ($L_0 = 0.6 \text{ mm}$), the analysis predicts droplet pinning while the DAF predicts $U_t = 2 \text{ mm/s}$. This feature of the numerical solutions has been discussed earlier [see, e.g., Koh et

al. (2009)], and arises from the need for a contact-line model that removes the singularity that arises at wetting lines. The use of a precursor film model means that although increasing computational grid refinement near the wetting line would reduce \(U_t\) for the Bo = 0.06 droplet, it is not capable of predicting pinning for such small droplets. Table 3 shows that the corresponding predictions of \(U_t\) for inertial flows are consistently larger than those for inertial flows, particularly for smaller droplets, and are much larger than those predicted by the analytical model. It also shows that ignoring inertia causes the droplets to relax to terminal velocity much more quickly than predicted either by the numerical solutions or by Eq. (3).

4.2 Effect of Substrate Orientation

Since droplets of pesticide solution can flow either on the upper, adaxial, or lower, abaxial, surfaces of foliage, it is of interest to know how substrate orientation affects droplet motion. Figure 6 show the corresponding predictions of the droplet shapes and the velocity of their center of mass with \(\alpha = 120^\circ\) for comparison with Fig. 4. It is clear that for these droplet sizes, which are representative of pesticide sprays, substrate orientation has very little effect on the evolution of the droplet shape. Figure 7 shows the effect of substrate orientation on the evolution of \(U_t\) for both inertial and inertialess droplet flows. For inertialess flow, abaxial orientation leads to slightly smaller terminal velocities for smaller droplets and slightly larger ones for larger droplets, while for inertial flows the abaxial orientation leads to slightly larger terminal velocities for all droplet sizes (see Table 5).

Finally, Fig. 8 studies the effect of substrate orientation and inertia on the relationship between Bo and Ca, which Eq. (6) predicts to be linear. The linear fit to the numerical predictions in Fig. 8 gives \(c_s = 133\) and \(\Delta = 0.09\) for \(Re_0 \neq 0\) and \(\alpha = 60^\circ\); \(c_s = 127\) and \(\Delta = 0.03\) for \(Re_0 = 0\) and \(\alpha = 60^\circ\); and \(c_s = 132\) and \(\Delta = 0.09\) for \(Re_0 \neq 0\) and \(\alpha = 120^\circ\). For inertialess flow the gradient of the line of best fit increases slightly for abaxial flows, whereas for inertial flow the lines are unaffected by substrate orientation and are in closer agreement with Eq. (6).

5. CONCLUSIONS

Since few previous studies have considered the dynamics of bio-pesticide-laden droplets on foliage, this work provides a number of important insights for the understanding of pesticide deposition. It has been shown that the use of EPNs at practical concentrations does not affect the VMD of bio-pesticide sprays, and the motion of the droplets formed can be modelled by neglecting the influence of the nematodes and assuming droplet homogeneity.

The computational results obtained generally support the insights provided by Eqs. (2)–(6), which include the effect of droplet parameters and leaf properties on (i) the minimum droplet size that will flow on foliage and (ii) the velocity and timescale of droplet motions, which determine their mobility and may influence the survivability of the nematodes. The computational results also demonstrate that, for realistic bio-pesticide-laden droplet sizes, the difference between adaxial or abaxial flows, for a given angle of inclination to the horizontal, is small. Comparison between the relatively simple analytical model and more complex three-dimensional computational solutions shows the former is consistent with corresponding experimental data provided by Podgorski et al. (2001), Le Grand et al. (2005), and Puthenveettil et al. (2013), and can predict the relationship between droplet migration velocity, viscous, hysteresis, and gravitational forces for gravity-driven flow reasonably well, provided droplet contact lines are smooth.

This investigation, which to the authors’ knowledge is the first to predict computationally the influence of flow inertia on three-dimensional droplet migration, shows inertia to have an important influence on both the timescale of relaxation to terminal conditions and the value of a droplet’s terminal velocity. For flows without inertia, droplets relax to terminal conditions very quickly and droplet footprints remain approximately circular as droplet size increases. In contrast, allowing for inertia in the numerical predictions leads to initial droplet elongation, which increases the relaxation time to terminal velocity significantly, in excellent agreement with theory. The inclusion of inertia also leads to DAF predictions of terminal droplet velocity that are consistent with the accompanying analysis, except for small droplets where the latter predicts droplet pinning while the wetting models employed in obtaining the corresponding DAF solutions result in a small, nonzero droplet velocity.
